THE THEORY OF THE TOP PARTNERS

1.1 THE STANDARD MODEL

The SM is a quantum field theory developed in the 1970s. It describes matter and the electromagnetic, weak and strong nuclear forces in terms of point-like particles.

The most profound insight in the SM is that all of these interactions are determined by symmetry principles, called local gauge symmetries. This idea is connected with the fact that the conserved physical quantities, e.g. electric charge, are conserved at every point in space-time, and not just globally. This connection is given by Nöther's theorem in the lagrangian formalism.

The treatment of one particular property of the particles requires some ingenuity. Mass terms are not allowed in the SM lagrangian, because they break the fundamental symmetry principles. Yet it is obvious from observation that most particles have mass. The Higgs mechanism with spontaneous symmetry breaking was devised to solve this problem, and appears to be close to experimental confirmation at the time of writing.

We will first review the features of the unbroken SM, then introduce the Higgs field and finally present some shortcomings of this theoretical description.

A complete description can be found elsewhere, the following section will highlight the material that is relevant to the problems we are investigating in the rest of our work.

1.1.1 *The unbroken SM*

All of the matter particles in the SM are fermions, and are usually divided in two categories: particles that feel the strong force, called *quarks*, and particles that do not, called *leptons*. Quarks and leptons are grouped into three *families* or *generations*. Particles from different generations have exactly the same properties, except for mass. The origin of this family structure is still unknown.

A force is introduced by requiring the lagrangian for the matter fields to be invariant under a group of space-time dependent transformations, called *gauge* transformations.

The theory of QED was the first successful gauge theory. It describes the electromagnetic force, with a $U(1)$ gauge invariance. As a consequence, a *gauge boson* has to be introduced to preserve the local symmetry, that is the photon.

The electromagnetic and weak forces are then unified by a gauge group $SU(2)_L \times U(1)_Y$, with the L subscript denoting the fact that the $SU(2)$ gauge transformations only involve the left-handed fermions. The Y subscript is intended to indicate that this $U(1)_Y$ group is not the same as the aforementioned group for QED. The number of gauge bosons must be the same as the dimension of the gauge group, so that we now get four vector bosons: the photon, the W^\pm and the Z.

The description of the strong force involves the group $SU(3)$. The charge of the strong force is called *colour*, it is carried by eight bosons called *gluons*. Figure 1 summarizes the particle contents of the unbroken SM.

Three Generations of Matter (Fermions)			
	I	II	III
mass→	2.4 MeV	1.27 GeV	171.2 GeV
charge→	$\frac{2}{3}$	$\frac{2}{3}$	$\frac{2}{3}$
spin→	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$
name→	u up	c charm	t top
	d down	s strange	b bottom
	v _e electron neutrino	v _μ muon neutrino	v _τ tau neutrino
	e electron	μ muon	τ tau
Bosons (Forces)			
	γ photon	g gluon	Z ⁰ weak force
	W [±] weak force		

Figure 1: The particles in the unbroken SM.

1.1.2 Spontaneous symmetry breaking: the Higgs mechanism

We have only considered massless particles. This is not the case for all the known fermions, and for the W and Z bosons. A mechanism was proposed to preserve the gauge invariance of the lagrangian, while the vacuum state is no longer a singlet under the action of the gauge group.

Spontaneous symmetry breaking of the local gauge symmetry in the SM provides massive W and Z bosons and a new boson, called the Higgs boson. In addition, we can obtain massive fermions by coupling them to the Higgs field with Yukawa terms.

1.1.3 The hierarchy problem

Recently found evidence for a light Higgs boson, with a mass near 125 GeV, are thought to be an indication of new symmetries and new particles beyond the SM.

The theory predicts that the mass m_H is subject to large radiative corrections from loop diagrams similar to figure 2, that should increase it by a large amount. In the SM, fine tuning is required to prevent this corrections from becoming too large. Theoretical physicists generally dislike this fine tuning on grounds of *naturalness*.

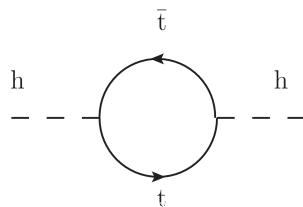

Figure 2: Radiative correction to the Higgs mass from the top quark.

The most notorious example of an extension to the SM that can eliminate this naturalness problem is supersymmetry, where the radiative corrections to the Higgs mass of the SM fermions are canceled by the contributions from their superpartners.

There exist many theories that do not invoke supersymmetry as the solution to the hierarchy problem. A robust and generic prediction of many of them is the existence of new particles, the top partners, again balancing the largest contribution to m_H coming from the top quark.

1.1.4 The top partners

Theoretical developments predicting the existence of top partners stem from the search for a way of introducing gravity in the SM, while solving the hierarchy problem at the same time.

Five-dimensional space-time theories including gravity can be formulated in terms of effective 4-d lagrangians where SM quarks mix with the top partners, which, again from arguments of naturalness, should have a mass below or slightly above the TeV scale. The lightest quarks have a small mass, indicating that their mixing with the new particles is negligible. The top quark, having a very large mass, should have a sizeable mixing with its partner, possibly making deviation from the SM top interactions detectable at the LHC.

We use the top partner model from [2] to describe our signal, with vertices with the vector bosons and the top quark. We study the possibility of observing the top partners in the very clean channel of two

same-sign hard leptons. Typical production and decay diagrams are shown in figure 3.

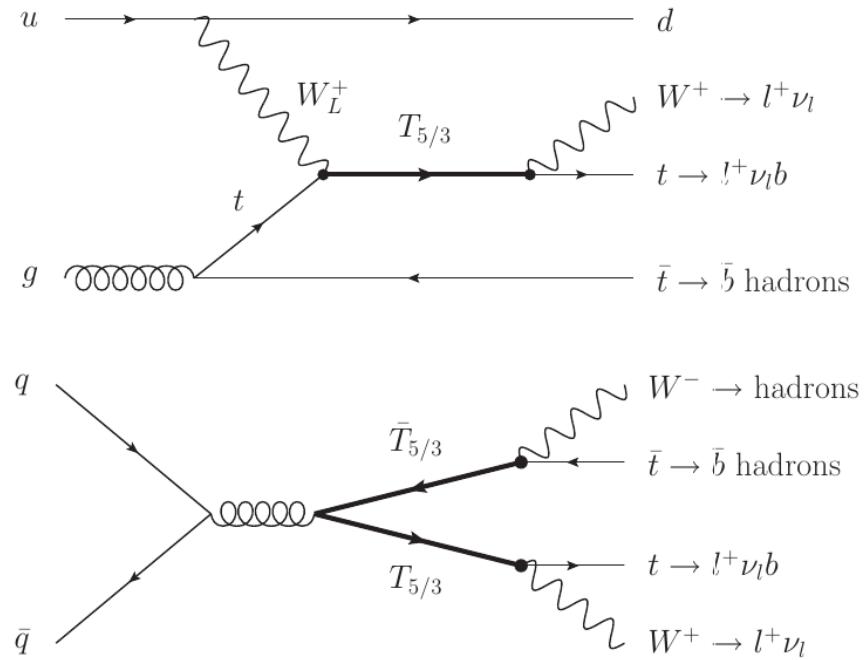

Figure 3: Typical single and pair production the top partner $T_{5/3}$ at the LHC.

2

THE LHC AND THE CMS DETECTOR

2.1 THE LARGE HADRON COLLIDER

The LHC is a ring-shaped proton-proton accelerator with a circumference of 27 km. It is hosted in a tunnel 45 to 170 m below ground at the CERN laboratory in Geneva, Switzerland. In 2011, the LHC accelerated two proton beams up to an energy of 3.5 TeV each and an instantaneous luminosity of up to $3.55 \cdot 10^{33} \text{ cm}^{-2}\text{s}^{-1}$.

The two proton beams are pre-accelerated through four smaller systems before being injected in the LHC:

- the linear accelerator (up to 50 MeV)
- the proton synchrotron booster (up to 1.4 GeV)
- the proton synchrotron (up to 26 GeV)
- the super proton synchrotron (up to 450 GeV)

The protons travel in ultra-high vacuum around 10^{-10} mbar, while different sets of magnets keep them in a circular orbit and provide acceleration and focusing.

Radio frequency cavities in the LHC accelerate the protons, providing an energy increase of 0.5 MeV/turn. Superconducting dipole magnets operate at currents of 11850 A to bend the trajectories of the protons with a magnetic field up to 8.3 T. Quadrupole magnets are employed to focus the beams, thus increasing the probability of an interaction when they collide. The magnets are cooled with superfluid helium at 1.9 K. The beams are made of “bunches” of protons with a time spacing of 75 ns.

At four different interaction points, the two proton beams are brought to collision where the experiments are located: CMS, ATLAS, LHCb and ALICE, as shown in figure 4. The first two are general purpose detectors. LHCb is designed for the study of CP violation in b physics, and ALICE for the analysis of the quark-gluon plasma produced mainly in heavy ion collisions.

2.2 THE COMPACT MUON SOLENOID

CMS is a general purpose detector based on interlocking cylindrical subdetectors in the central *barrel* region, closed by two *endcaps*, all placed coaxially with the beam and centred on the beam interaction point.

Figure 4: A view of the LHC and the four experiments.

2.2.1 Coordinate convention

The conventional coordinate system has its origin at the nominal interaction point. The z axis points along the beam direction, the y axis points vertically upwards, and the x axis points towards the centre of the LHC circumference. The xy plane is thus called the *transverse* plane as it is orthogonal to the CMS cylinder.

We define two angles in the transverse plane: the azimuthal φ angle is measured from the x axis, and the polar angle θ , measured from the z axis. *Pseudorapidity* is defined as $\eta = -\log \tan \theta/2$.

2.2.2 Structure of the detector

A global view and a transverse section of the detector are shown in figures 5 and 6.

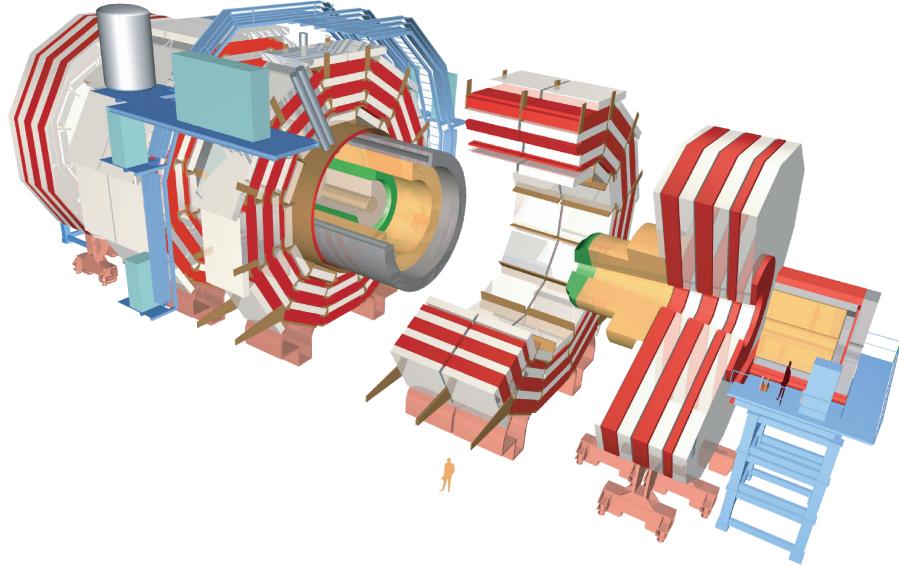

Figure 5: The CMS detector.

A superconducting solenoid 13.5 m and with a diameter of 5.9 m provides a uniform, axial magnetic field of 3.8 T. The return field sat-

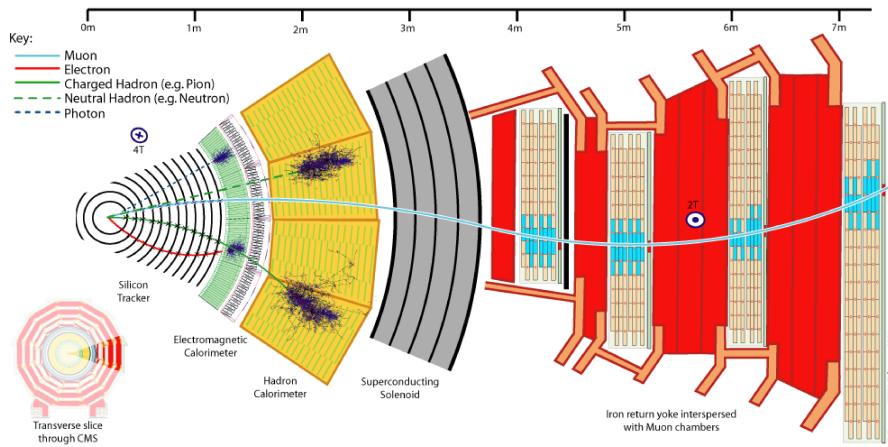

Figure 6: Transverse view of the CMS detector with some examples of tracks.

urates an iron yoke, which consists of five wheels in the barrel region and three disks in each of the two endcaps. Muon detectors are installed in the return yokes, with four stations of aluminium drift tubes in the barrel and cathode strip chambers with resistive plate chambers in the endcap.

The tracking system and the calorimeters are installed inside the solenoid. The tracker is a cylinder with a diameter of 2.6 m with three layers of pixel detectors, allowing exceptional measurements of the impact parameter of the particles and secondary vertex reconstruction, and ten layers of silicon microstrip detectors. The tracking system is surrounded by the calorimeters, which cover the region with $|\eta| < 3$. There is an electromagnetic calorimeter (ECAL), made of lead tungstate crystals and a brass/scintillator hadron calorimeter (HCAL). A forward calorimeter provides additional coverage up to $|\eta| < 5$.

2.2.3 The tracking system

Very high granularity and time resolutions are needed in the tough environment of the LHC experiments, with thousands of particles produced for every interaction. The high spatial resolution is particularly important in the region close to the primary interaction.

For these reasons, silicon detectors were chosen for the whole tracking system of the CMS experiment.

THE PIXEL DETECTOR is made of three cylinders in the barrel and two disks in each of the two endcaps. The spatial resolution on each hit is about $10 \mu\text{m}$ in $r\phi$ and about $20 \mu\text{m}$ in z .

THE MICROSTRIP DETECTOR is made of concentrical layers in the barrel region, divided in two systems: the *tracker inner barrel* (TIB) and the *tracker outer barrel* (TOB).

The TIB has four layers in the region with $20\text{ cm} < r < 55\text{ cm}$ and $|z| < 65\text{ cm}$. The sensors are 10 cm long in z , 80 to $120\text{ }\mu\text{m}$ wide and $320\text{ }\mu\text{m}$ thick. The single hit resolution is between 23 and $34\text{ }\mu\text{m}$ in the $r\text{-}\varphi$ plane, and about $230\text{ }\mu\text{m}$ in z .

The TOB module is made of six layers, covering $55\text{ cm} < r < 116\text{ cm}$ and $|z| < 116\text{ cm}$. The sensors have a length of 25 cm , a width of $180\text{ }\mu\text{m}$ and a thickness of $500\text{ }\mu\text{m}$. The single hit resolution is 35 to $52\text{ }\mu\text{m}$ in the $r\text{-}\varphi$ coordinates, and $530\text{ }\mu\text{m}$ in z .

Two more modules are installed in the endcaps, arranged around the beam line: the *tracker inner disks* (TID) and *tracker outer endcaps* (TEC)

Each TEC module consists of nine disks, while the TID have three smaller disks. Both these modules have strips pointing radially toward the beam line with a thickness of $320\text{ }\mu\text{m}$ to $500\text{ }\mu\text{m}$.

2.2.4 The electromagnetic calorimeter

The ECAL is the inner calorimeter, made of 61200 lead tungstate crystals in the barrel and 7324 crystals in the endcaps. The base of the crystals is about $2 \times 2\text{ cm}$ in size, with a depth of 23 cm , corresponding to 25 radiation lengths.

The scintillation light is collected by avalanche photodiodes in the barrel and vacuum phototriodes in the endcaps. They have a high gain and are insensitive to the magnetic field of the detector.

The energy resolution of the calorimeter has been measured in $Z \rightarrow ee$ events from the 2011 data [1], as shown in figure 7.

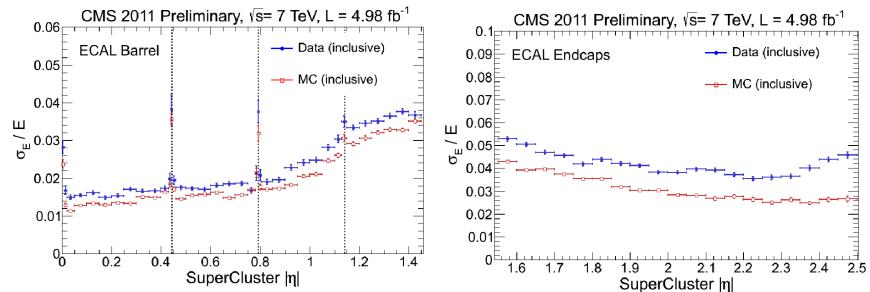

Figure 7: Energy resolution of the ECAL as measured in $Z \rightarrow ee$ events in the 2011 data.

2.2.5 The hadron calorimeter

The HCAL surrounds the ECAL and is made of plastic scintillators interleaved with brass layers. It is composed of a *hadron barrel* up to $|\eta| < 1.4$, a *hadron endcap* for $1.3 < |\eta| < 3.0$. Two more systems provide very good hermeticity: the *hadron outer calorimeter* is placed outside the magnet in order to measure the energy of penetrating hadrons, while the *hadron forward calorimeter* extends the coverage up to $|\eta| < 5$.

2.2.6 The muon detectors

The muon system is installed in the return yokes of the magnet. Concentrical cylinders cover the barrel region up to $|\eta| < 1.2$, while four disks make up the endcap detectors ($|\eta| < 2.4$). Three kind of gas detectors are employed: drift tubes in the barrel, cathode strip chambers id the endcaps, and resistive plate chambers in both. This last kind of detector has a fast response and is the most important for the trigger.

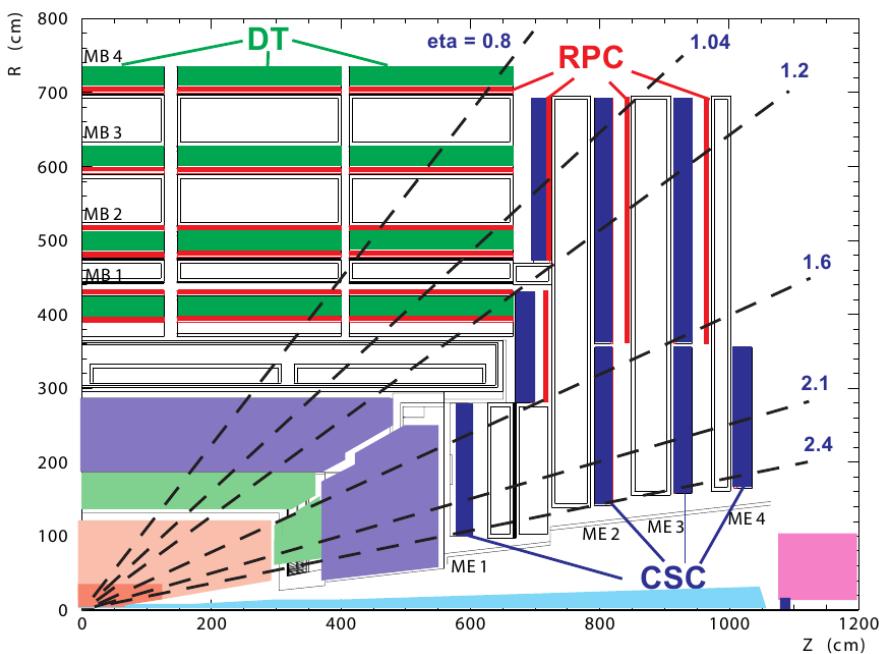

Figure 8: The layout of the muon detectors.

2.2.7 The trigger and data acquisition system

The design bunch spacing of the LHC is 25 ns, i.e. 40 MHz. About 100 interactions per second can be stored, so that the trigger has to provide a reduction factor of the order of 10^5 . The trigger system has two levels of selection: the *level 1* (L1) and the *high level trigger*.

L1 is a hardware trigger, made of processors close to the detector components. It exploits course granularity information from calorimeters and muon chambers to identify electromagnetic clusters, muons, jets and missing E_t . Its processing time per event is on the order of a microsecond. It reduces the rate of events to less than 100 kHz.

HLT is a software trigger run on a farm of commercial CPUs, and has access to all event data, allowing for precise object reconstruction and energy/momentum evaluation. The HLT processing time is around 0.1 s per event.
